Abstract

Magnetic properties of $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ ($0 \leq x \leq 0.5$) have been studied by magnetization measurements in low magnetic fields. It has been found that there exist spin-glass ($0 < x \leq 0.18$) and cluster-glass ($0.18 < x \leq 0.5$) regions. Ferromagnetic long-range order previously reported does not take place. Spin-glass behavior is ascribed to the frustration of random competing exchange interactions, namely the ferromagnetic double-exchange interaction between Co^{3+} and Co^{4+} and the antiferromagnetic one between like spins.

KEYWORDS: spin glass, cluster glass, magnetic phase diagram, magnetization, $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$

§1. Introduction

To elucidate the properties of strongly correlated electron systems many works on the electronic structure of 3 d transition metal oxides and metal-insulator transition by carrier doping have been made. Recently, LaCoO_3 and $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ have been studied in connection with the spin-state transition by means of soft-x-ray-absorption (XAS)¹⁾ and electron spectroscopies.²⁾ It has been revealed that LaCoO_3 is in the highly mixed character region between Mott-Hubbard and charge-transfer insulators. This finding is expected to provide new information to understand characteristic magnetic properties of these materials.

LaCoO_3 has been extensively studied in connection with the spin-state transition.¹⁻⁸⁾ This compound is a semiconductor with a conductivity gap of ~ 0.6 eV,²⁾ and has a rhombohedrally distorted perovskite structure. The most characteristic feature of magnetic properties is the unusual temperature dependence of magnetic susceptibility. The susceptibility shows an abrupt decrease below ~ 100 K, a broad maximum and a gradual reduction obeying approximately a Curie-Weiss law at higher temperatures.³⁻⁶⁾ The maximum was found not due to the onset of a magnetic long-range order by no observation of magnetic Bragg peaks below 100 K in neutron scattering measurements.⁷⁾ The characteristic feature of magnetic properties was explained by a model of the thermally populated high-spin state ${}^5T_2 (t_{2g}^4 e_g^2)$ located at approximately 0.01-0.08 eV above the low-spin state ${}^1A_1 (t_{2g}^6)$ for the trivalent cobalt ion.³⁻⁶⁾ The recent neutron scattering experiment also showed the temperature-induced cobalt magnetic moments which are explained by a thermally populated

high-spin model.⁸⁾ Furthermore, $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ has also been extensively investigated.⁹⁻¹⁴⁾ The effect of Sr doping is known to introduce a ferromagnetic long-range order even for small doping of $x=0.01$ and itinerant ferromagnetism for $x>0.2$. Nevertheless, it seems that such magnetic properties have not been satisfactorily explained up to now. Randomness and frustration which come from the change of the spin state due to the hole doping should be properly taken into account for the study of the present system.

We have made a detailed and careful study on magnetic properties of $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ ($0 \leq x \leq 0.5$) by magnetization measurements in low magnetic fields using a SQUID magnetometer. In the present study, we have confined ourselves to the Sr concentration range $0 \leq x \leq 0.5$, because the oxygen deficiency is known to increase above $x=0.5$, if samples are not prepared under high oxygen pressures.^{13,14)} In this study, we confirmed that the ferromagnetic behavior previously reported is not due to a ferromagnetic long-range order but spin-glass freezing. We present a new magnetic phase diagram of $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ ($0 \leq x \leq 0.5$).

§2. Experimental Procedure

$\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ polycrystalline samples used in present experiments were prepared by a solid state reaction method. The appropriate mixture of La_2Co_3 (4N), SrCO_3 (4N) and CoO (4N) was ground and calcined at 950°C for two days, and fired at 1300°C for about 10 days with about 10 intermediate grindings. Finally it was slowly cooled (about $100^\circ\text{C}/\text{day}$) from 950°C to room temperature in air. The samples were confirmed to be of a single

phase with the rhombohedrally distorted perovskite structure by powder x-ray diffraction analysis. Magnetization measurements were done by using a SQUID magnetometer (Quantum Design, model MPMS).

§3. Experimental Results and Discussion

3.1 LaCoO₃

Figure 1 shows the temperature dependence of magnetic susceptibility χ taken at 55 kOe. The result essentially agrees with the previous data.^{4,5)} Below ~ 25 K, χ follows the formula $\chi = C/(T - \Theta) + \chi_0$ with the Curie constant $C = 1.50 \times 10^{-4}$ K·emu/g, the Weiss constant $\Theta = -28.8$ K and $\chi_0 = 2.07 \times 10^{-6}$ emu/g. The recent NMR measurements¹⁵⁾ have shown that the Curie-Weiss behavior at low temperatures is not an intrinsic character. The temperature independent susceptibility χ_0 due to Van-Vleck orbital paramagnetism shows the nonmagnetic low-spin state 1A_1 as the ground state. Above ~ 25 K, χ increases rapidly with increasing temperature and exhibits a broad maximum at ~ 100 K as reported previously. To explain these characteristic features of χ , the recent XAS study¹⁾ provides a useful information on the spin-state transition of a trivalent cobalt. That is, LaCoO₃ is in a highly covalent low-spin state of 1A_1 up to ~ 420 K and exhibits a gradual transition to a mixed-spin state of the low-spin state and a high-spin one of 5T_2 at higher temperatures 420-650 K. Therefore, it is sufficient to take into account only the two-level population of the nonmagnetic ground 1A_1 ($S=0$) and the excited 5T_2 ($S=2$) states for understanding the broad maximum of χ at ~ 100 K as the previous analysis.^{6,16,17)}

3.2 Spin-glass region ($0 < x \lesssim 0.18$)

A doping of Sr below $x_c \sim 0.18$ introduces several changes in magnetic properties as mentioned below.

Figure 2 shows the temperature dependence of magnetization $M(T)$ for $x = 0.06, 0.09, 0.12$ and 0.15 . These data were taken in a field of 20 Oe after cooling from room temperature to the lowest temperature in a field of 20 Oe (FC) or in zero field (ZFC). In $M_{FC}(T)$ curves, a kink or plateau appears at $T_g = 15$ K ($x=0.06$), 33 K ($x=0.09$), 49 K ($x=0.12$) and 65 K ($x=0.15$), whereas a cusp is seen at T_g in $M_{ZFC}(T)$ curves, as is usually observed in spin-glass systems. T_g monotonously increases with increasing Sr concentration. The difference between $M_{FC}(T)$ and $M_{ZFC}(T)$ persists up to ~ 200 K in all samples.

Magnetization curves $M(H)$ taken after ZFC in fields up to 30 kOe are presented for $x=0.15$ in Fig. 3. At 5 K well below $T_g \sim 65$ K, the $M(H)$ curve after ZFC is of a characteristic S shape. On the other hand, the $M(H)$ curve at 65 K shows the presence of nonlinear susceptibility. These behavior of $M(H)$ is also one of the characteristic features in spin-glass systems.¹⁸⁾

We have observed a long-time nonexponential relaxation behavior of $M_{ZFC}(t)$ for $x=0.09$. The experimental procedure is as follows. After the ZFC process from room temperature to 6 K ($< T_g$), the sample was maintained in zero field for different waiting times $t_w = 0, 30$ and 300 min before application of a field of 100 Oe. As soon as the field was applied at time $t=0$, we measured magnetization $M_{ZFC}(t)$ as a function of time t . Figure 4 shows the M_{ZFC} vs. $\log(t)$ plot for $x=0.09$. The M_{ZFC} vs. $\log(t)$ plot has an inflection point at the time near the waiting time

t_w . This situation is more clearly seen in the $dM_{ZFC}/d\ln(t)$ vs. $\log(t)$ plot as shown in Fig. 5. The relaxation rate $dM_{ZFC}/d\ln(t)$ has a broad maximum at about t_w which is denoted by arrows for $t_w = 30$ and 300 min in Fig. 5. This characteristic behavior of $M_{ZFC}(t)$ is called the aging effect which was reported in other spin-glass systems.^{19,20)} Within the droplet scaling theory the aging effect is ascribed to the thermally activated growth of spin-glass-ordered domains.²¹⁾

Therefore, the experimental results mentioned above clearly reveal the onset of the spin-glass freezing at T_g in the Sr concentration range $0 < x \leq 0.18$. At present, however, we can not clarify the origin of the difference between M_{FC} and M_{ZFC} observed even well above T_g .

3.3 Cluster-glass region ($0.18 \lesssim x \leq 0.5$)

Further increasing Sr concentration over $x_c \sim 0.18$ introduces a magnetic phase different from the spin-glass phase.

As is shown in Fig. 6, M rapidly increases with increasing x from 0.15 to 0.2. M_{FC} at 20 Oe for $x=0.2$ shows a gradual increase bellow $T_g \sim 180$ K, whereas M_{ZFC} at 20 Oe deviates from M_{FC} bellow T_g and shows a broad maximum around ~ 160 K. Similar behavior is seen for $x=0.3, 0.4$ and 0.5 as presented in Fig. 6. M_{FC} for $x=0.5$, for example, rapidly increases in the temperature range just bellow $T_g \sim 245$ K and gradually does with further decreasing temperature, whereas M_{ZFC} exhibits a gradual reduction with decreasing temperature, following a pronounced increase near $T_g \sim 245$ K and a peak at ~ 240 K. This large difference between M_{FC} and M_{ZFC} bellow T_g indicates no simple ferromagnetic long-range

order in this Sr concentration range.

$M(H)$ was measured up to 55 kOe at several temperatures for $x=0.5$ as shown in Fig. 7. M at 6 K does not reach its saturation value even at 55 kOe, where magnetic moment per cobalt is $1.9 \mu_B$. As is shown in Fig. 8, Arrot plots of magnetization show a poor linear relation not observed in a simple ferromagnet, although the plots indicate the onset of spontaneous magnetization bellow $T_g \sim 245$ K. Such poor linear relation was previously observed a little bellow T_g in the measurement of $M(H)$ up to 10 kOe, although the measurement was analyzed on the basis of a ferromagnetic long-range order.¹²⁾

Another characteristic feature which indicates the absence of a ferromagnetic long-range order was also observed. Figure 9 shows the long-time relaxation of $M_{ZFC}(t)$ for three waiting times $t_w = 0, 30$ and 300 min in the $x=0.5$ sample, which was measured by the same procedure as mentioned in subsection 3.2. Also the corresponding relaxation rate $dM_{ZFC}(t)/d\ln(t)$ vs. $\log(t)$ for $x=0.5$ is presented in Fig. 10. Apparently, $M_{ZFC}(t)$ shows the long-time relaxation behavior not observed in ferromagnets. Furthermore, this long-time relaxation does not show such an aging effect observed in the spin-glass region.

In conclusion, samples in the Sr concentration region $0.18 \leq x \leq 0.5$ exhibit no long-range ferromagnetic order but show a cluster-glass behavior with the finite ferromagnetic spin correlation.

3.4 Magnetic phase diagram

On the basis of magnetization measurements mentioned above,

we constructed a magnetic phase diagram of $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ ($0 \leq x \leq 0.5$) as shown in Fig. 11. In this figure, solid circles in the Sr concentration range $0 < x \leq 0.18$ correspond to temperatures T_g where the spin freezing takes place. On the other hands, solid circles for $0.18 \leq x \leq 0.5$ represent onset temperatures T_g of the cluster-glass phase at which spontaneous magnetization sets in with the finite ferromagnetic correlation. Magnetization measurements clearly indicate the presence of phase boundary between spin-glass and cluster-glass phases at $x_c \sim 0.18$.

Now, we will consider exchange interactions between cobalt spins. The substitution of Sr^{2+} for La^{3+} converts its nearest neighbor cobalts into the tetravalent low-spin Co^{IV} (t_{2g}^5), high-spin Co^{4+} ($t_{2g}^3 e_g^2$) or intermediate-spin ($t_{2g}^4 e_g^1$) state. However, the electron spectroscopy study indicated that the doped hole has the lowest energy for the high-spin Co^{4+} state which has an energy approximately 1 eV lower than those of the low-spin Co^{IV} and the intermediate-spin state.²⁾ Below ~ 300 K, therefore, it is sufficient to consider only the high-spin Co^{4+} which is strongly hybridized by the charge-transfer state. Other cobalts will remain in the trivalent low-spin state Co^{III} (1A_1) having the high-spin Co^{3+} (5T_2) state located at about 0.01-0.08 eV above the low-spin state. The ferromagnetic double-exchange interaction is considered to be predominantly present between such trivalent and tetravalent cobalt spins.^{22,23)} The exchange interaction $J_{\text{Co}^{4+}-\text{Co}^{\text{III}}}$ between Co^{4+} and Co^{III} is also estimated to be ferromagnetic owing to Goodenough and Kanamori's rule.²⁴⁾ On the other hand, the superexchange interactions between high Co spins such as $J_{\text{Co}^{3+}-\text{Co}^{3+}}$ and $J_{\text{Co}^{4+}-\text{Co}^{4+}}$ are antiferromagnetic. Hence, we must

take account of randomness and competition between ferromagnetic and antiferromagnetic exchange interactions, which provide the spin-glass behavior observed for $0 < x \leq 0.18$. When the ferromagnetic exchange interactions overcome the antiferromagnetic one, the cluster glass appears at x_c . Frustration in the boundary between ferromagnetic clusters appears because of competition between ferromagnetic and antiferromagnetic exchange interactions, consequently preventing a ferromagnetic long-range order. If the Sr doping further increases over $x=0.5$, a ferromagnetic phase should appear, which includes an itinerant ferromagnet SrCoO_3 with Curie temperature $T_c = 222 \text{ K}$.¹³⁾

As regards conducting properties, replacing La with Sr bellow $x \sim 0.2$ introduces hole states above Fermi level E_F .²⁾ Further increasing Sr concentration over $x \sim 0.2$ makes these doped hole states overlap E_F , and results in the metallic phase. This metal-insulator transition is considered to closely correlate to the onset of the cluster glass, because the double-exchange mechanism results in itinerancy of the d electron. Also it may be related to the percolation concentration $x_p = 0.31$ calculated for the sc lattice with the nearest-neighbor interaction.²⁵⁾

§4. Conclusions

Magnetization measurements have been done to reveal in detail magnetic properties of $\text{La}_{1-x}\text{Sr}_x\text{CoO}_3$ ($0 \leq x \leq 0.5$). We constructed a magnetic phase diagram with characteristic features mentioned bellow.

(1) LaCoO_3 : The pronounced increase of χ was observed at

-100 K, corresponding to the thermally populated high-spin state of a trivalent cobalt ion.

(2) Spin-glass region ($0 < x \leq 0.18$): M_{ZFC} shows a cusp at the spin-glass freezing temperature T_g . Also we have observed the long-time relaxation of M_{ZFC} having the aging behavior below T_g .

(3) Cluster-glass region ($0.18 \leq x \leq 0.5$): Spontaneous magnetization appears below T_g with the finite ferromagnetic correlation. The long-time relaxation of M_{ZFC} and the large difference between M_{FC} and M_{ZFC} below T_g clearly indicate that a simple ferromagnetic long-range order does not take place.

In particular, it should be noted that the ferromagnetic long-range order previously reported for the small doping region does not exist because of the frustration between ferromagnetic double-exchange and antiferromagnetic superexchange interactions.
